

Outputs of all operations

1. Original

The Original operation displays the captured image without applying any processing. It is used as the reference for comparing the processed results.

2 Grayscale

The Grayscale operation converts a color image into a grayscale image. It represents the image using intensity levels from dark to bright, reducing the color information.

3 Binary

The Binary operation converts the grayscale image into two intensity levels: black and white. It uses thresholding to separate foreground and background regions.

4 HSV

The HSV operation converts the image into the Hue, Saturation, and Value color space. It separates color information from brightness information and is useful for color-based image analysis.

6 Contrast

The Contrast operation enhances the difference between dark and bright areas of the image. This makes image features and details easier to observe.

7 Erosion

The Erosion operation reduces the size of foreground regions in an image. It can remove small unwanted regions and shrink object boundaries.

8 Dilation

The Dilation operation expands foreground regions. It can help strengthen objects and fill small gaps in an image.

01

Dilation

Expands the white (bright) regions in the image using a structuring element.

02

Original Image

Displays the captured image without any processing.

03

Dilated Image

Bright regions are expanded, making objects appear thicker.

About Dilation

Dilation adds pixels to the boundaries of objects in an image. It is useful for connecting broken parts, filling small holes, and emphasizing bright regions.
